Contrary to the widely accepted picture of the dynamics of alkaline silicate solutions, tetramethylammonium silicate solutions require many days to re-establish thermodynamic equilibrium following a perturbation, as monitored by 29Si n.m.r. spectroscopy.

Aqueous alkaline silicate solutions are now known to contain a variety of low molecular weight silicate anions in dynamic equilibrium.1,2 In early studies it was widely believed that concentrated solutions required many days for their constituents to reach thermodynamic equilibrium following a perturbation, such as dilution or a change of pH.3 Lagerström4 in 1959 demonstrated that this notion is only correct for solutions that were in, or had passed through, an ‘instability range,’ characterised by an alkali to silica ratio low enough to allow colloidal silica to exist. Equilibrium is attained ‘very rapidly’ for solutions whose composition places them outside this range. His findings have since been confirmed by several workers,5 and recently Dent-Glasser and Lachowski,6 using trimethylsilylation followed by chromatographic separation, showed that sodium silicate solutions had returned to equilibrium within five minutes of being diluted, or undergoing a change in pH. Furthermore, Harris et al.7 have used 29Si n.m.r. spectroscopy to demonstrate that a very concentrated (7 M) sodium silicate solution reaches equilibrium within the time (1 h) taken to record its spectrum and, moreover, that the effects of heating a silicate solution are entirely reversible, again within the time required to record the spectrum. However, once the solution has reached equilibrium, chemical exchange between its constituents appears to be slow, and magnetisation transfer 29Si n.m.r. experiments8 give rate constants of the order of 0.5 kg mol⁻¹ s⁻¹ and a free energy of activation of 93 kJ mol⁻¹ for the dimerisation of the orthosilicate anion in a 2.8 mol kg⁻¹, 3.8 : 1 (K : Si) potassium silicate solution.

In recent years, considerable interest has been shown in alkaline silicate solutions prepared with an organic base, not least because of their role in zeolite synthesis.9 Tetramethylammonium silicate solutions, in particular, have received much attention, since it is believed10 that they may be, under some conditions, almost molecularly homogeneous, containing primarily the double four-membered (cubic octameric) silicate ring anion,11,12 [Si₆O₂₀]⁶⁻. Implicit in these investigations is the belief that, like their alkali-metal analogues, equilibrium between the anionic species in tetramethylammonium silicate solutions is rapidly established. We demonstrate...
below that this is not necessarily the case, and that equilibrium may be approached very slowly, even for solutions well outside the 'instability range'.

We show in Figure 1 the 99.32 MHz (11.7 Tesla) $^{29}\text{Si}$ n.m.r. spectrum of a tetramethylammonium silicate solution, 1 m in SiO$_2$, with a Si:N ratio of 1:2, obtained 16 days after the sample was prepared. Sample preparation details are given elsewhere. In agreement with previous work,$^{11,12}$ the intense low frequency signal is attributed to the cubic octameric cage silicate, and the weak high frequency signal is attributed to the monomeric SiO$_4^{4-}$ unit. (Throughout the following discussion, the spectral assignments used are based on those given by Harris and Knight$^{13}$ for a potassium silicate solution.) After the spectrum was recorded, the sample was heated to boiling for ca. 30 s in a polyethylene tube, quenched in liquid nitrogen, then allowed to reach room temperature and returned to the n.m.r. tube. The sample always appeared monophasic on thawing, and silica precipitation was not observed. Successive n.m.r. experiments [Figure 2, (a)-(e)] reveal the following. (i) During the first few minutes after thawing, the solution contains primarily monomeric silicate anions [Figure 2(a)], together with a small amount of the dimeric and cyclic trimeric species. The cubic octameric cage is not observed. (ii) The prismatic hexameric cage is the next species formed, followed, after several hours, by the cubic octameric cage [Figure 2, (b)-(d)]. (iii) The concentration of the cubic cage gradually increases at the expense of the other anions present. However, after almost two days at 20 °C this structure still accounts for less than 50% of the silica in solution, as shown in Figure 2(e), and the equilibrium situation is only re-established after several weeks.

We believe that this slow anion rearrangement in tetramethylammonium silicate solutions has not been appreciated prior to this work, and indicates the necessity of considering solution history, as well as composition, when analysing the structure and stability of its components.
